Abstract

Two observers based on high order sliding mode approach are proposed to determine the absolute orientation of a walking biped robot without feet. Contrary to velocities observers which have been often designed for robot control, very few works have been proposed for the orientation estimation: in this paper, the estimation of all state variables are derived from only the actuated joint variables. Then the technology problem of the absolute measurement is avoided. This latter point is an original contribution of this paper. The observers and the control law converge in finite-time and are well adapted for analysis of the cyclic walking gait. Then, a second original contribution consists in adapting an existing “simplified” Poincaré’s sections-based analysis of the stability of the walking to nonlinear systems with not fully available state variables.

1 Introduction

The legged robots have attracted the interest of many researchers since several decades. Vukobratovic\(^1\) proposed for the first time the well-known Zero-Moment Point (ZMP) in 1968, for the synthesis of walking gaits for bipeds.\(^2,3\) In 1977, optimal trajectories\(^4\) are designed for a bipedal locomotion using a parametric optimization. Formal’sky\(^5\) completely characterized the locomotion of anthropomorphic mechanisms in 1982. Sutherland and Raibert\(^6\) proposed their principle of virtual legs for walking robots in 1983.

The previously mentioned works are still used and adapted to more complex legged robots. Honda biped\(^7\) and HRP2 biped\(^8\) (Humanoid Robotics Project 2), which are probably, on the technological point-of-view, the most advanced biped robots, used the ZMP principle for their locomotion in 3D. Parametric optimization is used for walking and running reference trajectories design for a biped robot and non-actuated ankles quadruped one.\(^9,10\)

To our best knowledge, the main applications (handling, transport, ...) of legged robots are currently limited to the family of the statically stable robots as hexapod, quadruped ... The walking gaits of this family of robots is clumsy and slow. The limited use of nimble legged robots, which are dynamically stable, can be explained by the difficulties to define reference trajectories, to design control laws and to ensure the stability of the walking/running. These difficulties have several reasons: the constraints with the ground, which are unilateral, are difficult to analyze:\(^11\) the legged robots can loose contact with the ground during its displacement, or at the impacts; the tip of its stance feet can slide; the ground is not always regular, horizontal ... The problem of stability, connected with the gravity effects, of the legged robot must also be taken into account, as the autonomy in terms of energy. In order to overcome these difficulties, with dynamically stable legged robots, the bipeds are the object of many research works because there are well-adapted to the human environments. Trajectories are proposed for the walking of a biped robot, which is dynamically stable, in order to minimize the energy criteria\(^9,12,13\) and to improve the robot behavior. Walking reference trajectories,\(^14\) based on an inverted pendulum model, are checked on Aibo, the Sony’s dog robot, which is walking on its rear legs, as a biped with non-actuated ankles. The objective consists in...
starting from a stopped position and in reaching a cyclic gait. Another key point is the effect of the gravity on the bipedal walking: an accurate analyze of gravity for an experimental planar biped with five links, but with non-actuated ankles. *Rabbit* is done for a dynamically stable gait composed of single-support phases and passive impacts. A control law based on the zero dynamics equation is proposed.

In conclusion, the design of reference trajectories and control laws of biped robots, is a still challenging problem and will not be properly solved as long as the dynamics of the under interest robots is not thoroughly understood. Furthermore, the improvement of desired performances induces that the complexity of the control, based on the nonlinear model of the biped robots and using all their state coordinates, increases. Accurate sensors are necessary to measure the joint variables, the absolute orientation of a legged robot, the ground reactions. Unfortunately, a precise measurement of the absolute orientation of a walking robot in single support for example is, by a technical point-of-view, quite difficult to get. For example in a joint variable usually, a gearbox reducer leads to a more important accuracy of the encoder sensor, directly connected with the output axe of the actuator, to measure the joint angle.

Then, there is a real interest to develop observers in order to estimate absolute angular positions and velocities from only the knowledge of the relative angular variables. To our best knowledge, very few works have been done for the design of such observers, the previous works on observers design being done especially for the estimation of velocities (for noiseless differentiation) by supposing that all the angular variables are measured. A first attempt on the design of observer/controller using only the measurement of joint link angular variables (relative angles) for a three-link biped with no actuator in the ankles, in both cases of its stabilization in a vertical position and its walking, has been made by the authors and is based on high gain observers. This class of observers is based on the concept of uniform observability of nonlinear systems and their principle consists in reducing the effects of the nonlinear terms in the estimation error equation with a high gain correction. This approach gives an asymptotic convergence observer. Due to this latter property, no controller-observer superposition stability proof has been proposed: this proof is very difficult to establish for nonlinear systems for which the used observers are not finite-time convergent. An estimation of the absolute orientation of a two link biped without foot with a Kalman filter is done. Kalman and his co-authors designed an extended stochastic filter by linearizing the nonlinear system around the current state estimate.

The finite-time convergence property is one of the main characteristics of sliding mode observers (with robustness of estimation/observation versus uncertainties) whose dynamics depend on discontinuous output terms. However, this class of observers presents the main drawback of sliding mode, the chattering effect as the estimation error dynamics directly depend on a discontinuous function. This phenomena could generate high-frequency oscillations on observation, which could be negative for the control and the system. In the control context, in order to avoid this problem, in the 90’s, a solution has been given through the higher order sliding mode, which removes the sliding mode restrictions (chattering) while preserving its features (robustness, finite-time convergence) and improving the accuracy: in fact, the system dynamics do not directly depend on a discontinuous function. As standard sliding modes, higher order sliding mode approach has been used to design observers. Second order sliding mode observer, based on the twisting algorithm, is designed for an electrical motor: its robustness and its finite-time convergence are proved. A step-by-step higher order sliding mode observer ensures, step-by-step, the finite-time convergence of the estimation error to zero.

The current paper proposes two observer-based controllers of a three link biped, supposing that only the joint variables are available. To design this three-link biped, the physical parameters of a biped prototype *Rabbit*, which is a five link biped, are used. The originality of the present work is double:

- The observers are not only velocities observers, but also absolute position observers. Furthermore, two kinds of finite time convergent observers are used to solve this observation problem.
An important point of this work consists in the proof of the orbital stability of the biped walking. Original observers, based on second-order sliding mode control, are used. Coupled with a finite-time convergence controller, the use of this class of observers induces an extension of the Poincaré’s sections in one dimension for the stability of a biped gait with impulsive impact in the case where all the state is not available.

The article is organized as follows: the dynamical model of the robot is presented in Section 2. The control law is presented in Section 3. Section 4 is devoted to the observation problem. Definition of observability given in Subsection 4.1. A second order sliding mode observer, based on the twisting algorithm, with its associated canonical form in order to estimate the absolute orientation of the biped, is detailed in Subsection 4.2, as the asymptotic stability of the walking gaits. An alternative observer needing only the angular variables is presented in Subsection 4.3.

2 Model of the biped robot

The complete model of the biped robot consists in two parts: the differential equations describing the dynamics of the robot during the swing phase (these equations are derived using Lagrange’s method), and an impulse model of the contact event (the impact between the swing leg and the ground is modelled as an impulsive impact between two rigid bodies).

2.1 Swing motion equations

A planar three-link biped is considered (see Figure 1) and is composed by a torso and two identical legs without knee and foot. The joint between the torso and each leg is actuated by an actuator located in the hip. Then, the biped is underactuated in single support. The dynamic model is given by the following Lagrange equations

\[ D_e \ddot{q}_e + H_e \dot{q}_e + G_e = B_e \Gamma + D_R R \]

with \( q_e := [q^T \ x_t \ z_t]^T \) (the notation “ T ” means transposition). Vector \( q \) is composed by the joint variables and the absolute orientation of the torso, \( q := [\delta_1 \ \delta_2 \ \psi]^T \), and \((x_t, z_t)\) are the Cartesian coordinates of the center of mass of the torso (see Figure 1). \( D_e(q)(5 \times 5) \) is the symmetric positive inertia matrix. Matrix \( H_e(q, \dot{q})(5 \times 5) \) is the Coriolis and centrifugal effects matrix and \( G_e(q_e)(5 \times 1) \) is the gravity effects vector. \( B_e \) is a constant \( 5 \times 2 \)-matrix composed of 1 and 0 and \( D_R(q_e) \) is the \( 5 \times 2 \)-Jacobian matrix converting the external forces into the corresponding joint torques. \( \Gamma = [\Gamma_1 \ \Gamma_2]^T \) are the actuators torques. \( R = [R_{N1} \ R_{T1} \ R_{N2} \ R_{T2}]^T \) represents the ground reaction acting on the swing / stance leg tips. Assume that \( H_1 \) During the swing phase of the motion, the stance leg is acting as a pivot; the contact of the swing leg with the ground results in no rebound and no slipping of the swing leg.

Then, Equation (1) can be simplified and rewritten as

\[ D \ddot{q} + H \dot{q} + G = B \Gamma \]

As the kinetic energy of the biped is invariant under a rotation of the world frame, and viewed that \( \psi \) defines the orientation of the biped, the \( 3 \times 3 \)-symmetric positive inertia matrix is independent of this variable, i.e. \( D = D(\delta_1, \ \delta_2) \), \( H(q, \dot{q})(3 \times 3) \) is the Coriolis and centrifugal effects matrix, and \( G(q)(3 \times 1) \)
is the gravity effects vector. \( B(3 \times 2) \) is a constant matrix composed of 1 and 0. The \( D, H, G, \) and \( B \) are given in Appendix A. Equation (2) can be written as the nonlinear state system

\[
\dot{x} := \begin{bmatrix} D^{-1}(-H\dot{q} - G + BI) \end{bmatrix} \dot{\theta} = f(x) + g(q_{rel}) \cdot \Gamma
\]

with \( x := [\dot{q}^T, \dot{q}_{rel}^T]^T = [\delta_1, \delta_2, \psi, \delta_1, \delta_2, \psi]^T \) and \( q_{rel} := [\delta_1, \delta_2]^{T} \) the relative angles. The state space is taken such that \( x \in \mathcal{X} := \{x := [\dot{q}^T, \dot{q}_{rel}^T] \mid \dot{q} \in \mathcal{N}, q \in \mathcal{M}\} \), where \( \mathcal{N} = \{q \in \mathbb{R}^3 \mid |\dot{q}| < q_M < \infty\} \) and \( \mathcal{M} = (-\pi, \pi)^3 \). From these definitions, note that all the state variables are bounded.

### 2.2 Passive impact model

The impact occurs at the end of a single-support phase, when the swing leg tip touches the ground. Let \( T_I \) denote impact time. State the subscripts 2 for the swing leg and 1 for the stance leg during the single-support phase. An impact occurs when angle \( \delta_2 \) equals a desired value \( \delta_{2f} \), i.e. \( x \in S = \{x \in \mathcal{X} \mid \delta_2 = \delta_{2f}\} \). The choice of \( \delta_{2f} \) directly influences the length of the step. Assume that

- \( H_2 \) The impact is passive and absolutely inelastic,
- \( H_3 \) The swing leg touching the ground does not slip and the previous stance leg takes off the ground.
- \( H_4 \) At the impact, the angular positions are continuous, the angular velocities discontinuous.

Given these hypotheses, the ground reactions at the instant of the impact can be considered as impulsive forces acting on only the swing leg (leg 2) and defined by Dirac delta-functions \( R_2 = I_R \Delta(t - T) \), with \( I_R = [I_{R1}, I_{R2}] \) the vector of magnitudes of impulsive\(^2\) reaction for leg 2. Impact equations can be obtained through the integration of (1) for the infinitesimal time from \( T_I^- \) (just before the impact) to \( T_I^+ \) (just after the impact). The torques supplied by the actuators at the joints and Coriolis and gravity forces have finite values: thus, they do not influence the impact. Consequently, the impact equations can be written as

\[
D_e(\dot{q}_e^- - \dot{q}_e^-) = D_R I_R.
\]

\( q_e \) is the configuration of the biped at \( t = T_I \) (from \( H_4 \), this configuration does not change at the instant of the impact), \( \dot{q}_e^- \) and \( \dot{q}_e^+ \) are respectively the angular velocities just before and just after the impact. Furthermore, the velocity of the stance leg tip before the impact equals zero

\[
[\dot{x}_1(q_e^-, \dot{q}_e^-), \dot{z}_1(q_e^-, \dot{q}_e^-)]^T = 0_{2 \times 1}
\]

with \((x_1, z_1)\) the Cartesian coordinates of the stance leg tip. The swing leg after the impact becomes the supporting leg. Therefore, its tip velocity becomes zero after the impact

\[
[\dot{x}_2(q_e^+, \dot{q}_e^+), \dot{z}_2(q_e^+, \dot{q}_e^+)]^T = 0_{2 \times 1}
\]

with \((x_2, z_2)\) the Cartesian coordinates of the swing leg tip. The final result is an expression for \( x^+ := [\dot{q}^+T, \dot{q}^+T]^T \) (state just before the impact) in terms of \( x^- := [\dot{q}^-T, \dot{q}^-T]^T \) (state just after the impact) (for more details see the appendix B), which can be written as\(^2\) \( x^+ = \Delta(x^-) \).
2.3 Nonlinear model all over the step

The overall biped model can be expressed as a nonlinear system with impulse effects as

\[
\begin{align*}
\dot{x} &= f(x) + g(q_{rel}) \Gamma \\
\dot{x}^+ &= \Delta(x^-) \\
\dot{\delta} &= \dot{\delta}_2 \in \mathcal{S}
\end{align*}
\]

where \( \mathcal{S} = \{ x \in \mathcal{X} | \delta_2 = \delta_2 \} \).

3 Control law

The control for the walking gait\textsuperscript{26} consists in maintaining the angle of the torso at some constant value \( \psi_d \) and in controlling the swing leg such that it behaves as a mirror image of the stance leg, \( \theta_2 = -\theta_1 \) (see Figure 1). During the single-support phase, the degree of under-actuation equals one: only two outputs can be driven. Then, the robot gets a walking motion if the controller drives to zero the following outputs

\[
\dot{v} = \begin{bmatrix} v_1 \\
v_2 \\
v_3 \\
v_4 \end{bmatrix} = \begin{bmatrix} \psi - \psi_d \\
\theta_2 + \theta_1 \end{bmatrix} = \begin{bmatrix} h(x) \end{bmatrix}
\]

As the relative degree of each output component equals 2, and using standard Lie derivative notation,\textsuperscript{29} one gets \( \ddot{v} = L^2_h(x) + L_gL_fh(x) \Gamma \). The control consists in decoupling the system and in imposing a desired dynamic response. Note that, in \( \mathcal{X} \), the decoupling matrix \( L_gL_fh \) never equals zero. The control law \( \Gamma \) is then

\[
\Gamma := [L_gL_fh]^{-1}[-L^2_fh + w]
\]

to get a linear behavior of the output vector: \( \ddot{v} = w \). In the present work, the control law \( w \) is chosen to be finite time convergent, which could be done with, for example, sliding mode approach. The feedback function used in the present work comes from\textsuperscript{30}

\[
w = \Upsilon(v, \dot{v}) := \frac{1}{\varepsilon} \begin{bmatrix} \Upsilon_1(v_1, \varepsilon \cdot \dot{v}_1) \\
\Upsilon_2(v_2, \varepsilon \cdot \dot{v}_2) \end{bmatrix}
\]

Each function \( \Upsilon_i(v_i, \varepsilon \cdot \dot{v}_i) \), is defined as

\[
\Upsilon_i := -\text{sign}(\vartheta_i(v_i, \varepsilon \cdot \dot{v}_i)) \cdot |\vartheta_i(v_i, \varepsilon \cdot \dot{v}_i)|^{\frac{\alpha}{1 - \alpha}} - \text{sign}(\varepsilon \cdot \dot{v}_i) \cdot |\varepsilon \cdot \dot{v}_i|^{\alpha}
\]

with \( \vartheta_i(\cdot) = v_i + \frac{1}{\varepsilon} \text{sign}(\varepsilon \cdot \dot{v}_i) \cdot |\varepsilon \cdot \dot{v}_i|^{2 - \alpha} \) and \( 0 < \alpha < 1 \). The real parameter \( \varepsilon > 0 \) allows the settling time of the controllers to be adjusted.

4 Observer design

4.1 Analysis of observability

Consider the dynamical part of (7), with \( y \), the vector composed of the measured variables \( y := [y_1 y_2 y_3 y_4]^T = [\delta_1 \delta_2 \delta_1 \delta_2]^T \)

\[
\begin{align*}
\dot{x} &= f(x) + g(y_3, y_4) \Gamma \\
y &= \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 \end{bmatrix}
\end{align*}
\]

\[
\begin{pmatrix}
1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0
\end{pmatrix}
\]

\[
x
\]

\[
\begin{pmatrix}
C
\end{pmatrix}
\]
with \( x \in \mathcal{X}, \Gamma \in \mathbb{R}^2 \) and \( y \in \mathbb{R}^4 \). In the biped context, this model describes the swing motion and is studied over one step, i.e. for \( t \in [T_i^f, T_{i+1}^f] \), with \( T_i^f \) (resp. \( T_{i+1}^f \)) the initial (resp. final) impact time of the step \( i \). As \( g(y_3, y_4)\Gamma \), the input-output injection term of (11), is fully known, an observer for (11) can be designed by the following way. With abuse of notation, consider the next nonlinear system, which is the part of (11) without the input-output injection term

\[
\begin{align*}
\dot{x} &= f(x) \\
y &= Cx
\end{align*}
\]

Let \( O \) denote the generic observability space defined by

\[
O = \tilde{X} \cap \tilde{Y},
\]

with \( \tilde{X} = \text{Span}_{\mathcal{X}}\{dx\} \) and \( \tilde{Y} = \text{Span}_{\mathcal{X}}\{dy^{(j)}, j \geq 0\} \). \( \text{Span}_{\mathcal{X}} \) is a space spanned over field \( \mathcal{X} \) of meromorphic functions of \( x \). Function \( y^{(l)} \) denotes the \( l^{th} \) time derivative of \( y \).

**Definition 1** System (12) is generically observable if \( \text{dim } O = 6 \).

This condition is called **Rank condition of generic observability**. In fact, this definition has to be detailed, because the observability property of (12) depends on \( x \). As a matter of fact, the dimension of \( O \) can fail in \( \mathcal{X} \). Let \( \mathcal{T} \) denote an open set of \( \mathcal{X} \) such that the condition of the following definition fulfills.

**Definition 2** System (12) is observable if there exist \( \mathcal{T} \subset \mathcal{X} \) and 4 integers \( \{k_1, k_2, k_3, k_4\} \), called observability indices, such that

- \( k_1 \geq k_2 \geq k_3 \geq k_4 \) and \( \sum_{i=1}^{4} k_i = 6 \),

- The transformation

\[
\Phi(x) := \begin{bmatrix}
y_1 & \cdots & y_1^{(k_1-1)} & \cdots & y_4 & \cdots & y_4^{(k_4-1)}
\end{bmatrix}^T
\]

is a diffeomorphism for \( x \in \mathcal{T} \), which is equivalent to

\[
\text{Det} \left[ \frac{d\Phi(x)}{dx} \right] \neq 0 \text{ for } x \in \mathcal{T}.
\]

**Proposition 1** There exist \( \mathcal{T} \subset \mathcal{X} \) and \( [k_1 \ k_2 \ k_3 \ k_4]^T = [2 \ 2 \ 1 \ 1]^T \) such that system (12) is observable for \( x \in \mathcal{T} \).

**Sketch of proof** During the swing phase, and along the desired trajectories, the determinant of \( \frac{d\Phi(x)}{dx} \) crosses zero (see Figure 2). At this singular point, system (12) is not observable \( (x \in (\mathcal{X}/\mathcal{T}), the union of \( \mathcal{T} \) and \( \mathcal{X} \) without their intersection); elsewhere, system (12) is observable \( (x \in \mathcal{T} \subset \mathcal{X}) \).
4.2 Second-order sliding mode observer

In this subsection, a second order sliding mode observer is presented. The use of this class of observers is motivated by following reasons. First, as dual properties of sliding mode control, these observers have robustness and finite time convergence properties. Furthermore, the “second order” interest consists in the reduction of chattering phenomenon. Consider system (12) for \( x \in \mathcal{T} \). From Proposition 1, system (12) can be rewritten as

\[
\begin{bmatrix}
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0
\end{bmatrix} \begin{bmatrix}
z_1 \\
z_2 \\
z_3 \\
z_4 \\
z_5 \\
z_6
\end{bmatrix} + \begin{bmatrix}
0 \\
\varphi_2(z) \\
0 \\
\varphi_4(z) \\
0 \\
0
\end{bmatrix} = \begin{bmatrix}
y_1 \\
y_2 \\
y_3 \\
y_4
\end{bmatrix} = F(x).
\]

Observer design.

Suppose that there exists a system defined as

\[
\dot{\hat{z}} = A\hat{z} + \varphi(\hat{z}) + \chi(\hat{z}, y)
\]

which is an observer of (15), \( \hat{z} \) being the estimation of \( z \). Let \( \chi(\hat{z}, y) \) denote by \( \chi = [0 \ \varphi_2 \ 0 \ \varphi_4 \ \chi_5 \ \chi_6]^T \). One uses the standard sliding mode approach for \( \chi_5 \) and \( \chi_6 \), which reads as

\[
\begin{align*}
\chi_5 &= -\lambda_5 \text{sign}(\dot{\hat{z}}_5 - z_5) \\
\chi_6 &= -\lambda_6 \text{sign}(\dot{\hat{z}}_6 - z_6)
\end{align*}
\]

Then, from (16) and (15), the dynamics of estimation errors \( e_5 \) and \( e_6 \) read as (with \( e_j = \hat{z}_j - z_j, j = \{5, 6\} \))

\[
\begin{align*}
\dot{e}_5 &= e_1 - \lambda_5 \text{sign}(e_5) \\
\dot{e}_6 &= e_3 - \lambda_6 \text{sign}(e_6)
\end{align*}
\]

Then, \( e_5 \) and \( e_6 \) converge in finite time towards zero if the sliding condition \( \dot{e}_j e_j < 0 (j = \{5, 6\}) \) is fulfilled, i.e.

\[
\begin{align*}
\lambda_5 &> \text{Max}|e_1| = \text{Max}(|\dot{\hat{z}}_1 - \hat{z}_1|) \\
\lambda_6 &> \text{Max}|e_3| = \text{Max}(|\dot{\hat{z}}_2 - \hat{z}_2|)
\end{align*}
\]

Functions \( \chi_2 \) and \( \chi_4 \) are defined such that the estimation errors \( e_1, e_2, e_3 \) and \( e_4 \) converge towards zero in finite-time and read as

\[
\begin{align*}
\chi_2 &= -\Lambda_2 \text{sign}(e_1) \\
\chi_4 &= -\Lambda_4 \text{sign}(e_3)
\end{align*}
\]

Given that \( \dot{e}_1 = e_2 \) and \( \dot{e}_3 = e_4 \), one gets

\[
\begin{align*}
\ddot{e}_1 &= \varphi_2(\hat{z}) - \varphi_2(z) - \Lambda_2 \text{sign}(e_1) \\
\ddot{e}_3 &= \varphi_4(\hat{z}) - \varphi_4(z) - \Lambda_4 \text{sign}(e_3)
\end{align*}
\]
The choice for $\Lambda_2$ and $\Lambda_4$, based on the *twisting algorithm*\textsuperscript{23}, allows to ensure that the previous system converges to zero in finite-time, and then to ensure that $e_1, e_2, e_3$ and $e_4$ reach zero. The twisting algorithm ensures this convergence\textsuperscript{23,24} (for $j = \{1, 3\}$) if

\[
\begin{align*}
\Lambda_{j+1} &= \begin{cases} 
\lambda_{m}^{j+1} & \text{if } e_j \dot{e}_j \leq 0, \\
\lambda_{m}^{j+1} & \text{if } e_j \dot{e}_j > 0,
\end{cases} \\
\lambda_{m}^{j+1} &= \max(|\varphi_{j+1}(\hat{x}) - \varphi_{j+1}(x)|)
\end{align*}
\]

(22)

Then, a second-order sliding mode observer for (11) reads as

\[
\dot{x} = f(\hat{x}) + g(y_3, y_4)\Gamma + \left[\frac{d\Phi(\hat{x})}{dx}\right]^{-1} \chi(\hat{x}, y)
\]

(23)

is an observer of (11) with

\[
\chi(\hat{x}, y) = \begin{bmatrix} 0 \\ \chi_2 \\ 0 \\ \chi_4 \\ \chi_5 \\ \chi_6 \end{bmatrix} = \begin{bmatrix} 0 \\ \Lambda_2 \text{ sign}(\hat{x}_1 - y_1) \\ 0 \\ \Lambda_4 \text{ sign}(\hat{x}_2 - y_2) \\ \Lambda_5 \text{ sign}(\hat{x}_4 - y_3) \\ \Lambda_6 \text{ sign}(\hat{x}_5 - y_4) \end{bmatrix}
\]

(24)

**Remark 1** As observer (23) is based on the second and first orders sliding mode, it is applicable only for observability indices equal to 1 or 2. This restriction will be lax with the observer designed in Section 4.3.

**Remark 2** Observer (23) is designed for the swing phase. But, a step is composed of both swing and impact phases. At the impact event, the impact model is applied to the estimated state.\textsuperscript{31} Then, over one step, an observer of (7) reads as

\[
\begin{align*}
\dot{x} &= f(\hat{x}) + g(y_3, y_4)\Gamma + \left[\frac{d\Phi(\hat{x})}{dx}\right]^{-1} \chi(\hat{x}, y) \\
\hat{x}^+ &= \Delta(\hat{x}^-)
\end{align*}
\]

(25)

with $\hat{S} = \{\hat{x} \in \hat{X} | \hat{\delta}_2 = \delta_2 f\}$.

Around the singular point, i.e. $x \in (\mathcal{X}/\mathcal{T})$, it is necessary to adapt the observer, which is not valid at exactly the singularity. Two intuitive and quite natural solutions are proposed:

**Proposition 2** For $x \in (\mathcal{X}/\mathcal{T})$, observer (23) is turned into an estimator when $\det(\frac{d\Phi(\hat{x})}{dx}) = 0$, i.e.

\[
\dot{x} = f(\hat{x}) + g(y_3, y_4)\Gamma
\]

If the observer has not still converged when the singularity appears, there is discontinuity on observer dynamics. In the opposite case, there is no discontinuity viewed that the corrective term of the observer still equals zero. Note that, viewed that the observer is finite-time convergence one, the observer gain can be tuned such that the observer convergence time is smaller than the singularity moment. However, if one gets a high gain, troubles could affect system behavior through high level transients. To avoid the discontinuity appearing in the previous solution, a smooth corrective term is added at the observer.
Proposition 3 For $x \in X$, observer (23) is turned into the dynamic system (with $\Theta \in \mathbb{R}^{6 \times 6}$)

$$
\dot{x} = f(\hat{x}) + g(y_3,y_4)\Gamma + \Theta \chi(x,y)
$$

(26)

with

$$
\Theta = \begin{cases} 
\frac{1}{D_{\min}} \det \left[ \frac{d\Phi(\hat{x})}{dx} \right]^{-1} & \text{if } \det \left( \frac{d\Phi(\hat{x})}{dx} \right) \geq D_{\min} \quad \text{then } \hat{x} \in T \\
0_{6 \times 6} & \text{if } \det \left( \frac{d\Phi(\hat{x})}{dx} \right) = 0 \quad \text{then } \hat{x} \in (X/T)
\end{cases}
$$

(27)

with $D_{\min}$ a positive real arbitrarily stated by the user.

The choice of $D_{\min}$ is made in order that the condition number with respect to inversion of $\left[ \frac{d\Phi(\hat{x})}{dx} \right]$ is not “too much large”. Of course, this multiplication acts on observer gain values and implies that, around the singular point, the convergence conditions are not satisfied. It means that the singularity area must be “sufficiently small”.

4.2.1 Simulations

The parameters of the five-link biped prototype "Rabbit"\textsuperscript{15} are used to design the three-link biped parameters. The masses and lengths of the links (Indices 1, 2, 3: swing leg, stance leg, torso, resp.) are $m_1 = m_2 = 10 kg$, $m_3 = 16.3 kg$, $l_1 = l_2 = 0.8 m$, $l_3 = 0.625 m$. The distances between the joint and the mass center of each link are $s_1 = s_2 = 0.279 m$, $s_3 = 0.15 m$. The inertia moments around the mass center of each link are $I_1 = I_2 = 0.4006 kg\cdot m^2$, $I_3 = 2.0670 kg\cdot m^2$. The inertia of the rotor for each DC motor is $I = 3.32 \times 10^{-4} kg\cdot m^2$. The ratio of the gearbox reducers is equal to 50. Value $U$ of the applied torques equals 150N\cdot m. The control law described in Section 3 is applied with parameters $\alpha = 0.9$ and $\varepsilon = 20$ and is coupled to observer (26). The initial real and estimated values have been respectively stated as

$$
\begin{bmatrix} \delta_1, \delta_2, \psi, \delta_1, \delta_2, \psi \end{bmatrix} = \begin{bmatrix} -1.53, 1.53, -0.05, -2.9374, -2.4033, -0.6283 \end{bmatrix}
$$

$$
\begin{bmatrix} \hat{\delta}_1, \hat{\delta}_2, \hat{\psi}, \hat{\delta}_1, \hat{\delta}_2, \hat{\psi} \end{bmatrix} = \begin{bmatrix} -1.50, 1.50, 0.00, -2.8798, -2.3562, -0.5236 \end{bmatrix}
$$

Parameters $D_{\min}$ has been stated to 5, and the sliding mode observer parameters are $\lambda_m^2 = 10$, $\lambda_M^2 = 50$, $\lambda_m^4 = 10$, $\lambda_M^4 = 50$, $\lambda_5 = 1$, $\lambda_6 = 1$. The choice of observer and control law parameters has been made with respect to closed-loop dynamics and admissible maximum value for input (saturation). Figure 3 displays absolute position $\psi$ and the estimation error $\hat{\psi} - \hat{\psi}$ : the absolute position converges to the desired value $\psi_d$ and the estimation error converges towards zero before each impact. The same remark can be made for the absolute velocity $\dot{\psi}$ and the estimation error $\dot{\psi} - \dot{\hat{\psi}}$ (Figure 4). Figure 5 displays walking over several steps.

4.2.2 Stability

In this section, the objective is to prove the asymptotic stability of the walking of the biped controlled by controller (8) coupled with observer (26). An important result is that the stability\textsuperscript{26} can be proven on the basis of a restriction of the Poincaré’s map to a one-dimensional manifold. This section proposed an original extension of this latter result to observer-based controlled systems. As the “real” state vector is not fully measured, the “real” zeros dynamics and impact surface manifolds can not be used in the stability proof,
the idea is then to suppose that the estimated state is on “estimated” zeros dynamics and impact surface manifolds. The finite-time convergence of the observer and controller, at the end of the first step, ensures that the estimated manifolds are the same than “real” ones. Then, it is possible to use the standard reduced Poincaré’s approach to establish, over the second step, the stability.

**Sketch of the stability proof.** The stability proof is made over two steps (see Figure 6). The first step consists in making the observer converge to real system before the impact, and also in making the control objectives fulfill before the impact. Then, at the end of the first step, the observer and the controller have converged. During the second step, it is then possible to apply the simplified Poincaré’s approach.

**Notations.** The impact time at the end of the $i^{th}$ step is noted $T_i^j$ and is taken as the time origin for the $i+1^{th}$ step. Let $T_i^O$ the convergence (towards 0) time of the estimation error over the $i^{th}$ step and $T_i^C$ the convergence time of the controller over the $i^{th}$ step. The observer and the controller have been tuned such that $T_i^O \leq T_i^C < T_i^j$, i.e. the observer converges faster than the controller over the step $i$ (Figure 6). As the observer converges to real state in finite time, it is obvious that $T_i^O = 0$ for $i > 1$: then, from $T_i^O$, one has $\hat{x} = x$ (see Figure 6).

**Numerical procedure.** Let $\hat{Z}$ denote the “estimated” zero dynamics manifold, $\hat{Z} = \{ \hat{x} \in \hat{X} \mid h(\hat{x}) = 0, \dot{h}(\hat{x}) = 0 \}, \hat{S}$ the “estimated” impact surface manifold, $\hat{S} = \{ \hat{x} \in \hat{X} \mid \hat{\delta}_2 = \delta_2 \}, \hat{X} = \{ \hat{x} := [\hat{\eta}^T, \hat{\eta}^T]^T \mid \hat{\eta} \in \mathcal{N}, \hat{\eta} \in \mathcal{M} \}$, $\hat{\eta}$ and $\hat{\eta}$ being the estimated values of $q$ and $\eta$. The conditions required to define the restricted Poincaré map are :

1. $\hat{S} \cap \hat{Z}$ is a smooth sub-manifold of $\hat{X}$. It is equivalent to the fact that the map

$$
\begin{bmatrix}
    h(\hat{x}) \\
    \dot{h}(\hat{x}) \\
    \hat{\delta}_2
\end{bmatrix} =
\begin{bmatrix}
    \psi - \psi_d \\
    \hat{\theta}_1 + \hat{\theta}_2 \\
    \psi \\
    \hat{\theta}_1 + \hat{\theta}_2 \\
    \hat{\delta}_2
\end{bmatrix}
$$

has constant rank equal to 5 on $\hat{S} \cap \hat{Z}$, which is obvious to prove. If $(\hat{\eta}, \hat{\eta}) \in \hat{S} \cap \hat{Z}$, $\hat{\eta}$ equals a constant, denoted $\hat{\eta}_0$. Let $\gamma := [h(\hat{x})^T \hat{\theta}_1(\hat{x})]^T$ which has full rank at $\hat{\eta}_0$. On $\hat{Z}$, one has $h(\hat{x}) = 0$

$$
\begin{bmatrix}
    0 \\
    \hat{\theta}_1
\end{bmatrix} = \frac{\partial \gamma}{\partial \hat{\eta}} \hat{\eta}_0
$$

**Proposition 4 :** Let us define $p$, a diffeomorphism from $\mathcal{R} \rightarrow \hat{S} \cap \hat{Z}$ to complete equation (29) with the configuration vector $q_0$ of the impact such as:

$$
p(\hat{\theta}_1) = \begin{bmatrix}
    \frac{\partial \gamma(\hat{\eta}_0)}{\partial \hat{\eta}} \\
    \hat{\eta}_0
\end{bmatrix}^{-1} \hat{\theta}_1
$$

2. The decoupling matrix $L_x L_f h(\hat{x})$ is invertible on $\hat{X}$.

3. The cross section for the Poincaré map will be taken to be $\hat{S}$, the “estimated” impact surface. Define $\lambda : \mathcal{R} \rightarrow \mathcal{R}$ computed by the following manner
Let \( \hat{\delta}_1(T_0^0) < 0 \) denote the initial estimated angular velocity just before the initial impact. Compute \( \hat{x}^-(T_1^0) := p(\hat{\delta}_1(T_0^0)) \), the estimated state vector of the robot before the impact. State the real state before the impact as (given that \( \delta_1, \delta_2 \) and the corresponding velocities are measured)

\[
x^-(T_1^0) := \left[ \hat{\delta}_1(T_1^0) \hat{\delta}_2(T_1^0) \psi^- (T_1^0) \delta_1^-(T_0^0) \delta_2^-(T_0^0) \psi^-(T_1^0) \right]^T
\]

\[
x^-(T_1^0) := \left[ y_1^-(T_1^0) y_2^-(T_1^0) \psi^- (T_1^0) y_3^-(T_1^0) y_4^-(T_1^0) \psi^-(T_1^0) \right]^T
\]

- Apply the impact model to \( \dot{x}^- (T_0^0) \) (resp. \( x^- (T_0^0) \)), then we obtain \( \dot{x}^+(T_1^0) = \Delta(\dot{x}^- (T_0^0)) \) (resp. \( x^+(T_1^0) = \Delta(x^- (T_0^0)) \)).

- Use \( x^+(T_1^0) \) as the initial condition in (7) controlled by (9) which uses \( \dot{x} \). Simulate until one of the following happens:
  
  **a)** There exists a time \( T_1^1 \) for which \( \hat{\delta}_2 = \delta_2 \) and \( T_0^1 \leq T_1^1 < T_1^2 < \infty \), we apply again the impact model to \( \dot{x}^- (T_1^1) \), then we obtain \( \dot{x}^+(T_1^1) = \Delta(\dot{x}^- (T_1^1)) \). At this time, the real and estimated state variables have same values, viewed that the observer has finite-time convergence of estimation error, and that the observer gains have been tuned such that \( T_0^1 < T_1^2 \). Use \( \dot{x}^+(T_1^1) \) as the initial condition in (7) controlled by (9). If there exists a time \( T_1^2 \) for which \( \hat{\delta}_2 = \delta_2 \) such that \( T_0^2 \leq T_1^2 < T_1^2 < \infty \), then \( \lambda \left[ \hat{\delta}_1^- (T_1^1) \right] := \hat{\delta}_1^- (T_1^2) \); else \( \lambda \left[ \hat{\delta}_1^- (T_1^1) \right] \) is undefined at this point.

  **b)** There does not exist a \( T_1^2 > 0 \) such that \( \hat{\delta}_2 = \delta_2 \); in this case, it is also true that \( \lambda \left[ \hat{\delta}_1^- (T_1^1) \right] \) is undefined at this point.

In order to determine if the closed-loop system is stable, function \( \lambda \) is evaluated for \( \hat{\delta}_1^- (T_1^0) \in [-3, -0.5], \psi \in [0.8 \cdot \psi_d, 1.2 \cdot \psi_d] \) and \( \psi \in [-0.1, 0.1] \). Figure 7 displays function \( \lambda : \lambda \) is undefined for \( \hat{\delta}_1^- (T_1^1) \) less than -2.4 rad/s and more than -1.1 rad/s. A fixed point appears at approximately \( \hat{\delta}_1^- (T_1^1) = -1.63 \text{rad/s} \), and corresponds to an asymptotically stable walking cycle. Figure 8 displays \( \hat{\delta}_1^- (T_1^0) \) in terms of initial estimation errors on unmeasured variables \( \psi (T_0^0) \in [0.8 \cdot \psi_d, 1.2 \cdot \psi_d] \) and \( \psi (T_0^1) \in [-0.1, 0.1] \). For each point of this 3D-area, the estimated state variable converges to real ones, the control outputs reach zero before the end of each step, and the biped converges to a stable limit cycle. In terms of this 3D-area, the asymptotically stable walking cycle corresponds to the star point.

### 4.3 Step-by-step observer

In order to reduce the number of sensors or to limit the noise introduced by the differentiation (for computation of velocity), the measurements concern now only the joint variables. Of course, it implies that the previous observer is not usable, as the observability indices are now at least equal to 3, and that, the previous observer strategy, the observability indices must be lower or equal to 2. In this section, the observer is based on triangular form one. Consider system (12) with the outputs \( \begin{bmatrix} y_1 & y_2 \end{bmatrix}^T = [\delta_1 \delta_2]^T \): an observability indices pair is \( [k_1 \ k_2]^T = [3 \ 3]^T \), i.e. there exists \( T_{33} \subset X \) such that, \( \forall x \in T_{33}, z = \Phi_{33}(x) = [z_1 z_2 z_3 z_4 z_5 z_6]^T := [y_1 y_1 \bar{y}_1 y_2 y_2 y_2]^T \) is a state coordinates transformation. Under this latter transforma-
tion, system (12) can be rewritten as
\begin{align}
    \dot{z}_1 &= z_2 \\
    \dot{z}_2 &= z_3 \\
    \dot{z}_3 &= f_3(z) \\
    \dot{z}_4 &= z_5 \\
    \dot{z}_5 &= z_6 \\
    \dot{z}_6 &= f_6(z) \\
\end{align}
(31)

4.3.1 Observer design

An observer\(^{25}\) for (31) reads as
\begin{align}
    \dot{\hat{z}}_1 &= \hat{z}_2 + E_1(t)\chi_1 \\
    \dot{\hat{z}}_2 &= \hat{z}_3 + E_2(t)\chi_2 \\
    \dot{\hat{z}}_3 &= f_3(\hat{z}) + E_3(t)\chi_3 \\
    \dot{\hat{z}}_4 &= \hat{z}_5 + E_4(t)\chi_4 \\
    \dot{\hat{z}}_5 &= \hat{z}_6 + E_5(t)\chi_5 \\
    \dot{\hat{z}}_6 &= f_6(\hat{z}) + E_6(t)\chi_6 \\
\end{align}
(32)

with \(\hat{z} := [\hat{z}_1 \hat{z}_2 \hat{z}_3 \hat{z}_4 \hat{z}_5 \hat{z}_6]^T\) the estimated vector of \(z\). Suppose that the initial error between the estimated and real vector is bounded. The principle of this class of observers consists in forcing, each in turn, estimated state variables to corresponding real ones, in finite time. The finite time convergence property is based on an adequate choice of \(E_j(t)\) and \(\chi_j\) (\(j = \{1, \cdots, 6\}\)), i.e. \(E_j(t)\) and \(\chi_j\) are defined such that each estimation error \(e_j = \hat{z}_j - z_j\) converges to zero in finite time. One gets

- Function \(\chi_i\) \((i = \{1, 4\})\) is based on the twisting algorithm\(^{23}\) and reads as
  \(\chi_i = -\Lambda_i \text{ sign}(\hat{z}_i - z_i)\)
  (33)

with
\begin{align}
    \Lambda_i &= \begin{cases} 
    \lambda^i_m & \text{if } e_i \hat{e}_i \leq 0 \\
    \lambda^i_M & \text{if } e_i \hat{e}_i > 0 
    \end{cases} \\
    \lambda^i_m &= \text{Max}(|e_{i+1}|) \\
    \lambda^i_M &= 3\lambda^i_m \\
\end{align}
(34)

- Function \(\chi_j\) \((j = \{2, 3, 5, 6\})\) uses the standard sliding mode approach and reads as
  \(\chi_j = -\lambda_j \text{ sign}(\hat{z}_j - \tilde{z}_j)\)
  (35)

with \(\lambda_j > 0\), and
\(\tilde{z}_j = \hat{z}_j + E_{j-1}(t)\chi_{j-1}\)
(36)

The estimation error dynamics is
\begin{align}
    \dot{e}_1 &= e_2 + E_1(t)\chi_1 \\
    \dot{e}_2 &= e_3 + E_2(t)\chi_2 \\
    \dot{e}_3 &= f_3(\hat{z}) - f_3(z) + E_3(t)\chi_3 \\
    \dot{e}_4 &= e_4 + E_4(t)\chi_4 \\
    \dot{e}_5 &= e_5 + E_5(t)\chi_5 \\
    \dot{e}_6 &= f_6(\hat{z}) - f_6(z) + E_6(t)\chi_6 \\
\end{align}
(37)
with \( e_j = \tilde{z}_j - z_j, \ j = \{1, \cdots, 6\} \). The following steps display the determination of \( E_j \) and the proof of finite time convergence.

- **Step 1.** Suppose that \( e^i_t(0) \neq 0 \ (i = \{1, 4\}) \). Observer (32) is initialized such that \( E_1 = E_4 = 1 \) and \( E_2 = E_3 = E_5 = E_6 = 0 \). The error dynamics reads as

\[
\begin{align*}
\dot{e}_1 &= e_2 + \chi_1 \\
\dot{e}_2 &= e_3 \\
\dot{e}_3 &= f_3(\hat{z}) - f_3(z) \\
\dot{e}_4 &= e_5 + \chi_4 \\
\dot{e}_5 &= e_6 \\
\dot{e}_6 &= f_6(\hat{z}) - f_6(z)
\end{align*}
\]

(38)

As \( \chi_j \) is based on the twisting algorithm with appropriate tuning of \( \Lambda_j \), \( e_j \ (j = \{1, 4\}) \) reaches zero in finite time at \( t = t_j \). Then, \( \forall t \geq t_j, e_j(t) = \dot{e}_j(t) = 0 \), i.e.

\[
e_j = 0 \quad \dot{e}_j = e_{j+1} + \chi_j = \hat{z}_{j+1} - z_{j+1} + \chi_j = 0
\]

(39)

From (39), one gets \( \hat{z}_{j+1} + \chi_j = z_{j+1} \) and from (36), \( z_{j+1} = \tilde{z}_{j+1} \).

- **Step 2.** For \( t \geq t_j \), one states \( E_j = E_{j+1} = 1 \) and \( E_3 = E_6 = 0 \). From (35)-(39), dynamics of \( e_2, e_3, e_5 \) and \( e_6 \) read as

\[
\begin{align*}
\dot{e}_2 &= e_3 - \lambda_2 \text{sign}(e_2) \\
\dot{e}_3 &= f_3(\hat{z}) - f_3(z) \\
\dot{e}_5 &= e_6 - \lambda_5 \text{sign}(e_5) \\
\dot{e}_6 &= f_6(\hat{z}) - f_6(z)
\end{align*}
\]

(40)

By tuning \( \lambda_i > \text{Max}(|e_{i+1}|) \ (i = \{2, 5\}) \), a finite time convergence to \( e_i = 0 \) is ensured at \( t = t_i \). Then, \( \forall t \geq t_i, e_i(t) = \dot{e}_i(t) = 0 \), i.e.

\[
\begin{align*}
e_1 &= 0 & \dot{e}_1 &= 0 \\
\dot{e}_2 &= e_3 + \chi_2 = 0 \\
\dot{e}_4 &= 0 \\
\dot{e}_5 &= e_6 + \chi_5 = 0
\end{align*}
\]

(41)

From the second line of (41), one gets \( \hat{z}_{i+1} + \chi_i = z_{i+1} \) and from (36), \( z_{i+1} = \tilde{z}_{i+1} \).

- **Step 3.** For \( t \geq t_i \), one states \( E_j = 1 \ (j = \{1, \cdots, 6\}) \). From (35)-(41), dynamics of \( e_3 \) and \( e_6 \) reads as

\[
\begin{align*}
\dot{e}_3 &= f_3(\hat{z}) - f_3(z) - \lambda_3 \text{sign}(z_{3} - z_3) \\
\dot{e}_6 &= f_6(\hat{z}) - f_6(z) - \lambda_6 \text{sign}(z_{6} - z_6)
\end{align*}
\]

(42)

By tuning \( \lambda_i > \text{Max}(|f_i(\hat{z}) - f_i(z)|) \ (i = \{3, 6\}) \), a finite time convergence to \( e_i = 0 \) is ensured, which implies a finite time convergence of the observer.

Then, a finite time convergence observer for (32) reads as

\[
\hat{z} = A_{33}\hat{z} + F_{33}(\hat{z}) + \chi_{33}(\cdot)
\]

(43)
with
\[ A_{33} := \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad F_{33}(\hat{z}) := \begin{bmatrix} 0 \\ f_3(\hat{z}) \\ 0 \\ f_6(\hat{z}) \end{bmatrix} \quad \chi_{33}(\cdot) := \begin{bmatrix} E_1 \chi_1 \\ E_2 \chi_2 \\ E_3 \chi_3 \\ E_4 \chi_4 \\ E_5 \chi_5 \\ E_6 \chi_6 \end{bmatrix} = \begin{bmatrix} -E_1 \lambda_1 \text{sign}(\hat{z}_1 - y_1) \\ -E_2 \lambda_2 \text{sign}(\hat{z}_2 - \hat{z}_{2}) \\ -E_3 \lambda_3 \text{sign}(\hat{z}_3 - \hat{z}_3) \\ -E_4 \lambda_4 \text{sign}(\hat{z}_4 - y_2) \\ -E_5 \lambda_5 \text{sign}(\hat{z}_5 - \hat{z}_5) \\ -E_6 \lambda_6 \text{sign}(\hat{z}_6 - \hat{z}_6) \end{bmatrix} \]

Loss of observability.

During the swing phase, along the nominal trajectories, \( \det \left[ \frac{d \Phi_{33}(x)}{dx} \right] \) crosses zero (see Figure 9). Of course, as in the previous case, it induces a problem for the observer design. A solution, which could not be used in the previous case, is to design the observer with an other pair of observability indices. As a matter of fact, \( \{k_1, k_2\} = \{4, 2\} \) is also eligible: there exists \( T_{42} \subset X \) such that, \( \forall x \in T_{42} \), the function \( z = \Phi_{42}(x) = [z_1 z_2 z_3 z_4 z_5 z_6]^T = [y_1 y_1 y_1^3 y_2 y_2]^T \) is a state transformation. The same observer design approach then previously is used for the design of a finite time convergence observer with \( \{k_1, k_2\} = \{4, 2\} \); then, one gets
\[
\hat{x} = A_{42} \hat{x} + F_{42}(\hat{z}) + \chi_{42}(\cdot)
\]
with
\[ A_{42} := \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad F_{42}(\hat{z}) := \begin{bmatrix} 0 \\ f_4(\hat{z}) \\ 0 \\ f_6(\hat{z}) \end{bmatrix} \quad \chi_{42}(\cdot) := \begin{bmatrix} E_1 \chi_1 \\ E_2 \chi_2 \\ E_3 \chi_3 \\ E_4 \chi_4 \\ E_5 \chi_5 \\ E_6 \chi_6 \end{bmatrix} = \begin{bmatrix} -E_1 \lambda_1 \text{sign}(\hat{z}_1 - y_1) \\ -E_2 \lambda_2 \text{sign}(\hat{z}_2 - \hat{z}_{2}) \\ -E_3 \lambda_3 \text{sign}(\hat{z}_3 - \hat{z}_3) \\ -E_4 \lambda_4 \text{sign}(\hat{z}_4 - \hat{z}_4) \\ -E_5 \lambda_5 \text{sign}(\hat{z}_5 - y_2) \\ -E_6 \lambda_6 \text{sign}(\hat{z}_6 - \hat{z}_6) \end{bmatrix} \]

For this latter choice of observability indices, there is also loss of observability but not in the same conditions than previously (see Figure 9). Then, the observation strategy can be described as follows:

Observation algorithm.

Let \( T_{SW} := \text{Min}(t) \) such that \( t \in [T_i^l, T_i^{l+1}] \) and \( \det \left[ \frac{d \Phi_{33}(x)}{dx} \right] (t) = 0 \). Then, one has
- For \( t \in [T_i^l, T_{SW}] \), the observer is designed with \( \{k_1, k_2\} = \{3, 3\} \),
- From \( t \in [T_{SW}, T_i^{l+1}] \), the observer is designed with \( \{k_1, k_2\} = \{4, 2\} \).

The following proposition displays the design of a finite time convergence observer for (11).

**Proposition 5** A finite time convergence observer for the nonlinear system (11) reads as
\[
\hat{x} = f(\hat{x}) + g(y)\Gamma + M\chi(\cdot)
\]
with
\[
M\chi(\cdot) = \begin{cases} \left[ \frac{d \Phi_{33}(\hat{x})}{d \hat{x}} \right]^{-1} \chi_{33} & \text{for } t \in [T_i^l, T_{SW}] \text{ then } \hat{x} \in T_{33} \\ \left[ \frac{d \Phi_{42}(\hat{x})}{d \hat{x}} \right]^{-1} \chi_{42} & \text{for } t \in [T_{SW}, T_i^{l+1}] \text{ then } \hat{x} \in T_{42} \end{cases}
\]
with $T^i_i$ the initial impact time of the step, $T^{i+1}_i$ the impact time at the end of the step, and $T_{SW} := \text{Min}(t)$ such that $t \in [T^i_i, T^{i+1}_i]$ and $\text{Det} \left[ \frac{d\Phi_{33}(\hat{x})}{dx} \right](t) = 0$.

### Practical point-of-view.

- The commutation from the first observer structure to the second one is made through the condition that $T_{SW} := \text{Min}(t)$ such that $t \in [T^i_i, T^{i+1}_i]$ and $\text{Det} \left[ \frac{d\Phi_{33}(\hat{x})}{dx} \right](t) = D_{SW}$, where $D_{SW} > 0$ a real fixed by the user (see Figure 10). The choice of $D_{SW}$ is made in order that the condition number with respect to inversion of $\left[ \frac{d\Phi_{33}(\hat{x})}{dx} \right]$ is not "too much large".

- The finite-time convergence observer previously exposed ensures that the estimation errors exactly converge to zero. In practice, this property is ensured for a neighborhood of zero which the estimation errors are forced to reach and to stay in.

#### 4.3.2 Simulations

The control law described in Section 3 is tuned with $\alpha = 0.9$ and $\varepsilon = 20$. The desired value for $\psi$ is stated as $\psi_d = -0.5236 \text{ rad}$. The value $\delta_{2f}$, which defines the length of the step and also the impact event, is stated as $\delta_{2f} = -2.3562 \text{ rad}$. The parameter $D_{SW}$ has been tuned to 5. For $\{k_1, k_2\} = \{3, 3\}$ and $\{k_1, k_2\} = \{4, 2\}$ the observer parameters are respectively

- $\lambda^1_m = 2$, $\lambda^1_M = 10$, $\lambda_2 = 2$, $\lambda_3 = 60$, $\lambda^4_m = 2$, $\lambda^4_M = 10$, $\lambda_5 = 2$, $\lambda_6 = 10$
- $\lambda^1_m = 2$, $\lambda^1_M = 10$, $\lambda_2 = 2$, $\lambda_3 = 60$, $\lambda_4 = 600$, $\lambda^5_m = 2$, $\lambda^5_M = 10$, $\lambda_6 = 2$

The observer and the control law parameters have been tuned such that the observer convergence time is smaller than the control law convergence time, which is smaller than the impact event. The initial real and estimated values have been respectively stated as

\[
\begin{bmatrix}
\hat{\delta}_1(0), \hat{\delta}_2(0), \psi(0), \delta_1(0), \delta_2(0), \psi(0)
\end{bmatrix} = 
\begin{bmatrix}
-1.725, 1.725, 0.0, -2.8798, -2.3562, -0.6021
\end{bmatrix}
\]

\[
\begin{bmatrix}
\hat{\delta}_1(0), \hat{\delta}_2(0), \hat{\psi}(0), \delta_1(0), \delta_2(0), \hat{\psi}(0)
\end{bmatrix} = 
\begin{bmatrix}
-1.500, 1.500, 0.0, -2.8798, -2.3562, -0.5236
\end{bmatrix}
\]

One supposes that there are initial estimation errors on absolute variable and also on the relative velocities, which are not measured, and that these initial (estimated and real) state variables have been stated such that the biped robot reaches a stable walking cycle. Figure 11 displays absolute position and the corresponding estimation error which converges to zero before each impact. This is also the case for $\dot{\psi}$ and its estimation error $\dot{\psi} - \hat{\dot{\psi}}$ (Figure 12). The control law has been tuned such that the control output vector $y$ equals zero before the impact ($\psi$ reaches desired value $\psi_d$, see Figure 11-top), and the biped reaches a stable periodic cycle after several steps (see Figures 13 and 14). As shown by Figure 14, during the first step, two phenomena are acting. First, the estimated state variables are converging to real values which induces a large transient over the first step only (as the observer is tuned such that the estimation error equals zero before the end of the first step). Once the observer has converged, the control law ensures that the biped robot reaches a stable walking cycle, as the initial conditions have been adequately chosen.

In order to evaluate the robustness properties of the observer, a numerical test has been realized with an additive Coulomb friction in the biped model. These frictions are essentially located in the gearbox reducers. Then, model (2) is modified such as

\[
D\ddot{q} + C\dot{q} + G = B\Gamma - \Gamma_{\text{rot}} \text{sign}(q_{\text{rel}})
\]  

(47)
The design of observers and control law does not take into account the Coulomb friction. Therefore, this friction is acting as a perturbation for robustness tests. The nominal value of the Coulomb friction is $\Gamma_{rot} = 2N\cdot m$. The initial real and estimated values are defined by (47). Figure 15 displays walking cycles over several steps. The walking gait converges to a stable cycle, which characterizes the robustness of the observer-based control.

5 Conclusion

The measure of the absolute orientation of mobile robots such as dynamically stable biped is difficult to obtain. However its knowledge is useful for the control during the locomotion. Then we proposed in this paper, a solution, based on the observation of the state vector. Two observers are designed to estimate the absolute orientation of a biped, one from the knowledge of actuated positions and velocity and one from the knowledge of actuated joint variables only, for a walking gait composed of single-supports and impacts. The main property of the observers and the control law is the finite-time convergence, which allows to ensure its convergence before each impact and provide the existence of a cyclic gait. Then, these observers are well adapted to the problem of the cyclic gait. The observers coupled with a finite time convergence controller induce an attraction basin, from which stable walking gait establishment is possible and proved. The fact leads to think that experiments with a prototype are realistic. The future objectives consist to extend these results to a five link biped prototype.

\]
Remark 3 The symmetric positive inertia matrix $D$ is independent of the orientation of the biped ($\psi$).

B Impact Model

The impact equations 4 and an additional set of two equations is obtained from the condition that the swing leg does not rebound or not slip at impact, $D_\text{R}\ddot{q}_e^+ = 0$ become

$$
\begin{bmatrix}
D_e & -D_R^T \\
D_R & 0_{2\times2}
\end{bmatrix}
\begin{bmatrix}
\dot{\ddot{q}}_e^+ \\
\dot{\ddot{q}}_e
\end{bmatrix}
= 
\begin{bmatrix}
D_e\ddot{q}_e \\
0
\end{bmatrix}
$$
